Appendix A: Construction of spending in the app data

This appendix discusses the data and provides details on how we prepare the data for analyses.

We received anonymized data directly from the personal financial management service provider (app). The process by which the company acquires the data can differ across users, account providers (e.g., Bank of America, Wells Fargo) and time. For some account providers, the data are scraped from the website of an account provider, and in other cases a direct feed is received from the account provider. All account numbers and other personal identifying information is removed by the app company before we receive the data. Otherwise, we receive the data exactly as it is received by the app. The table below summarizes the key variables in the data that are used in our analysis:

User_id	-	Anonymous identifier constructed by the personal financial management service
Posted_date	-	Date a transaction was recorded
Account_Provider_Id	-	An identifier for a specific account provider (e.g. Bank of America)
Account_Type	-	An indicator for whether an account is a checking account, savings account, credit card, or other account.
Transaction_Amount	-	The amount of the transaction
Is_Credit	-	Whether the transaction was a credit or a debit
Transaction_Description	-	A string variable describing the transaction.

Our cleaning processes proceeds in steps outlined below:

I. Remove likely duplicates +/- 3 days

Because the data may include pending transactions, a given spending may show up multiple times in different transactions. For instance, if a transaction was pending on one day, and posted the next day, we could see a duplicate recording of the same transaction in the data, which would not reflect actual spending.

Some account providers indicate whether a transaction is pending or posted, and we first remove all transactions that are flagged as pending, or contain the word “pending” in the transaction string. Since many account providers do not indicate whether a transaction is pending, and since this information also varies across time, we deal with this problem by removing transactions that are duplicates on the dimensions of {User_Id, Account_Provider_Id, Account_Type, Is_Credit, Transaction_Amount, Transaction_Description} over a 3 day window. This removes approximately 5% of transactions. Some of these transactions could be non-

duplicates (for instance, if someone buys the exact same item every day), and so these transactions will also be removed by this procedure. Using the data with likely duplicates removed, we next proceed to calculate total spending and total income, which we aggregate to the weekly level.

II. Construct variables used in analysis and aggregate to weekly level

The transactions contain every single inflow and outflow from a household's account, some of which are not "consumption." Two problematic types of transactions are transfers across accounts and credit card payments. In most cases, transfers across accounts can be identified from the transaction strings, since they are commonly flagged as "transfer," "xfer," "tfr," "xfr" or "trnsfr." We remove all transactions with these words appearing in their description.

Credit card payments reflect lagged spending that we have already included in our measure of total spending, since we can see the individual purchases that make up the credit card payment on the credit card. Therefore, we wish to identify and remove these payments. We identify credit card payments as debits appearing on a non-credit-card account that also appears as a credit to a credit card, and remove these.

We also remove the largest transaction greater than \$1,000 in a weekly window, since these transactions appear to be predominantly credit card payments and transfers missed by our procedure. As a caveat, this likely also removes mortgage payments (committed spending), extremely large durables purchases (such as a down payment on a car, although we would still see car payments), and payments on tax liabilities. To summarize, our measure of "total spending" used in this paper is defined as:

$$\{\text{Total spending}\} = \{\text{Total Account Debits}\} - \{\text{Flagged Duplicates}\} - \{\text{Transfers}\} - \{\text{Credit Card Payments}\} - \{\text{Largest Transaction} > \$1,000 \text{ (if any)}\}.$$

Finally, we address the issue of accounts that become unlinked from the app or are not properly synchronising. If an account goes out of sync for a period of up to two weeks, the app will generally be able to backfill these transactions. Longer periods will result in missing spending. Unfortunately, there is no indicator in the data when an account is not syncing. We identify non-syncing credit cards as cards that carry an account balance for longer than a month, but have no interest charges or payments. To ensure the quality of our spending data, we drop users in the weeks where credit cards that ever amounted to 10 percent or more of their overall weekly spending are flagged as nonsyncing based on the above criteria.

Appendix B: Machine Learning Classification of Transactions

As discussed in Appendix 1, the data we receive contain raw transaction strings. These transaction strings differ across account providers in their context. We wish to identify spending that comes from gasoline. Identifying to which of a set of categories an observation belongs, based on information in the transaction descriptions, is a classic “classification” problem in machine learning.

We seek a simple machine learning (ML) model to identify gasoline spending in the data. For this to work, we require a “training” set of data containing observations whose category membership is known. Fortunately, two account providers in our data categorize the transactions into merchant category codes (MCCs) directly in the transaction strings. These two cards represent about 3% of all transactions. As discussed in the text, it is virtually impossible to separate out our main MCC of interest, 5541, “Automated Fuel Dispensers” from MCC code 5542, “Service Stations,” which in practice covers gasoline stations with convenience stores.¹ Because distinguishing gasoline purchases classified as 5542 or 5541 is nearly impossible with the information in transaction descriptions,² we group transactions with these two codes together.

Before proceeding with the details of the machine learning model, it is useful to discuss an alternative approach that identifies all gasoline stations in the data through string matching techniques. To see why this is infeasible, consider that the 100 most popular gasoline station strings cover approximately 50% of the total market share in the transactions where we know the MCC codes. Scaling up is costly: to get 90 percent of the market share, we would need to search for over 30,000 strings (Appendix Figure 1). Moreover, since other spending can often have similar transaction descriptions, it is hard to know what strings minimize noise while maximizing predictive power. The machine learning algorithm thus helps discipline the approach of what transaction strings contain the most useful information. The machine learning procedure proceeds in 3 steps: training, testing, and application.

Machine learning requires both a “training” data set—data actually used to fit a classification model—and a “testing” data set to evaluate the out of sample performance of the model. In the training step, we build a prediction model using data with the MCC codes (i.e. data

¹ To be clear, “Service Stations” do not include services such as auto repairs, motor oil change, etc.

² E.g., a transaction string with word “Chevron” or “Exxon” could be classified as either MCC 5541 or MCC 5542.

where classification is known). We use the larger of the two account providers as the training data set, and test the performance of the model on the smaller account. We explicitly set aside the second card as the training data set because transaction strings, which we will feed into the model to classify the data, can differ across account providers. Therefore, if we train on data from the two accounts, we may fit our two cards extremely well, but we may have a poor “out of sample” fit of our model.

The classification algorithm we use is known as a random forest classifier, which fits a number of separate decision trees. A decision tree is a series of classification rules that ultimately lead to a classification of a purchase as gasoline or not. The rules, determined by the algorithm, minimize the decrease in accuracy when a particular model “feature” is removed. The features we use are the transaction values and individual words in the transaction strings (this approach is known as “bag of words”), after some basic string cleaning. We limit the number of features to 20,000 words, and transaction amounts rounded to the nearest 50 cents. An example decision tree is shown in Appendix Figure 2.

In this example, the most important single word is “oil.” If a transaction string contains the word oil, the classification rule is to move to the right, otherwise the rule is to move to the left. If the string does not contain the word oil, the next most important single word is “exxonmobil.” The tree keeps going until all the data are classified.

Whether a transaction is classified as gasoline spending or not is simply the majority vote over a number of decision trees. This is known as a “white box algorithm” because the model determines optimal decision rules that we can see. We use prebuilt packages from the python machine learning toolkit.³

The results of the model are shown in Appendix Table B.1. The model predicts $292,997 / (292,997 + 26,553) = 92\%$ of automated fuel dispenser and service station transactions. The ratio of misclassifications to correct classifications is $(30,080 + 26,553) / 292,997 = 19\%$.

In summary, the ML approach is able to correctly classify over 90% of gasoline spending in the test data. If a human were to do this, she would need to identify over 30,000 strings. In

³ [Scikit-learn: Machine Learning in Python](#), Pedregosa *et al.*, JMLR 12, pp. 2825-2830, 2011.

addition, the model correctly classifies over 99.5% of the gasoline stations that would have been captured in an alternative approach of identifying the 100 largest gasoline stations by market share.

Appendix Figure B.1

Appendix Table B.1. Confusion Matrix

		Actual gasoline spending	
		No	Yes
Predicted gasoline spending	No	2,741,524	26,553
	Yes	30,080	292,997

Notes: Table shows the four possible outcomes for our testing data set which is not used in any way to train the model, as described in the text. The rows “Predicted gasoline spending” refer to the binary prediction from the model as not gasoline, “no,” or gasoline, “yes”. Actual gasoline refers to the “truth,” which is known for the case of our testing dataset.

Appendix C. Additional Tables and Figures

Appendix Figure C.1. Distribution of Ratio of Gasoline to Non-Gasoline Spending, 2013Q1-2014Q4

Note: the figure shows the quarterly gasoline to non-gasoline spending distribution in the app data and the CEX interview survey (solid lines), and the same ratio calculated over all of 2013 (dashed lines).

Appendix Figure C.2. Dynamics of gasoline prices across metropolitan areas

Notes: The figure plots time series of gasoline prices (all types) to major metropolitan areas. All series are from the FRED© database (mnemonics: CUUR0000SETB01, CUURA422SETB01, CUURA320SETB01, CUURA207SETB01, CUURA318SETB01, CUURA101SETB01) and normalized to be equal to 100 in 2010.

Appendix Table C.2. Gelman et al. (2014)

Table 1. Check versus ACS demographics (percent). The sample size for Check is 59,072, 35,417, 28,057, and 63,745 for gender, age, education, and region, respectively. The sample size for ACS is 2,441,532 for gender, age, and region and 2,158,014 for education.

	Check	ACS
<i>Sex</i>		
Male	59.93	48.59
Female	40.07	51.41
<i>Age</i>		
18–20	0.59	5.72
21–24	5.26	7.36
25–34	37.85	17.48
35–44	30.06	17.03

Appendix D: Marginal Propensity to Consume in Partial Equilibrium versus General Equilibrium Effects

In this appendix, we link the marginal propensity to consume (MPC) to structural parameters and explore how partial equilibrium MPC is potentially related to general equilibrium effect of gasoline price changes. In this exercise, we vary the price of gasoline holding everything else constant.

Partial equilibrium

Consumer a household that solves the following problem

$$\begin{aligned} \max & m(c_1) + u(c_2) - v(L) \\ \text{s.t.} & c_1 + p_2 c_2 = wL \end{aligned}$$

where c_1 is the numeraire good (or “non-gasoline spending”; we normalize $p_1 = 1$), c_2 is “gasoline”, L is labor, w is wages, and functions m, u, v describe how the household values goods and leisure. In a popular case, $m(c_1) = c_1$ so that the utility is quasi-linear. Because this is a partial equilibrium model, we take wages as given.

The first-order conditions yield:

$$\begin{aligned} m'(c_1) &= \lambda \\ u'(c_2) &= p_2 \lambda \\ v'(L) &= w \lambda \end{aligned}$$

After log-linearization of these FOCs and the budget constraint, we have (assume w is fixed)

$$\begin{aligned} \check{c}_1 &= \epsilon_1 \check{\lambda} \\ \check{c}_2 &= \epsilon_2 (\check{\lambda} + \check{p}_2) \\ \frac{v''(L)L}{v'(L)} \check{L} &= \eta^{-1} \check{L} = \check{\lambda} \\ \check{c}_1 &= \frac{wL}{c_1} \check{L} - \frac{p_2 c_2}{c_1} (\check{p}_2 + \check{c}_2) = (1+s) \check{L} - s(\check{p}_2 + \check{c}_2) \end{aligned}$$

where $s \equiv \frac{p_2 c_2}{c_1}$ and $\frac{wL}{c_1} = \frac{c_1 + p_2 c_2}{c_1} = 1 + s$ and $\eta = \left(\frac{v''(L)L}{v'(L)} \right)^{-1}$ is the Frisch labor supply elasticity, $\epsilon_2 \equiv \frac{u'(c_2)}{u''(c_2)c_2} < 0$ and $\epsilon_1 \equiv \frac{m'(c_1)}{m''(c_1)c_1} < 0$. Note that the first two conditions imply that $\check{c}_2 = \frac{\epsilon_2}{\epsilon_1} \check{c}_1 + \epsilon_2 \check{p}_2$.

It follows that

$$\begin{aligned} \check{c}_1 &= (1+s) \check{L} - s(\check{p}_2 + \check{c}_2) = (1+s) \eta \check{\lambda} - s \left(\frac{\epsilon_2}{\epsilon_1} \check{c}_1 + (1+\epsilon_2) \check{p}_2 \right) \\ &= \frac{(1+s)\eta}{\epsilon_1} \check{c}_1 - s \left(\frac{\epsilon_2}{\epsilon_1} \check{c}_1 + (1+\epsilon_2) \check{p}_2 \right) = \left\{ \frac{(1+s)\eta}{\epsilon_1} - s \frac{\epsilon_2}{\epsilon_1} \right\} \check{c}_1 - s(1+\epsilon_2) \check{p}_2 \Rightarrow \\ \check{c}_1 &= - \frac{s(1+\epsilon_2)}{1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1}} \check{p}_2 = - \frac{s(1+\epsilon_2)}{\left\{ 1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1} \right\} \times s \times (1+\epsilon)} \times s \times (1+\epsilon) \times \check{p}_2 \Rightarrow \end{aligned}$$

$$d \log C = - \frac{s(1 + \epsilon_2)}{\left\{1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1}\right\} \times s \times (1 + \epsilon)} \times s \times (1 + \epsilon) \times d \log P_{gas}$$

where $(1 + \epsilon)$ is estimated from the regressing $d \log (p_2 c_2)$ on $d \log p_2$. Note that this equation provides structural interpretation of our specification (2) in the paper.

We know from the derivation above that

$$\begin{aligned} d \log (p_2 c_2) &= \check{c}_2 + \check{p}_2 = \frac{\epsilon_2}{\epsilon_1} \check{c}_1 + (1 + \epsilon_2) \check{p}_2 \\ &= - \frac{\epsilon_2}{\epsilon_1} \frac{s(1 + \epsilon_2)}{1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1}} \check{p}_2 + (1 + \epsilon_2) \check{p}_2 \\ &= \frac{(1 + \epsilon_2) \left(1 - \frac{(1+s)\eta}{\epsilon_1}\right)}{1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1}} \check{p}_2 \end{aligned}$$

So that $(1 + \epsilon) = \frac{(1 + \epsilon_2) \left(1 - \frac{(1+s)\eta}{\epsilon_1}\right)}{1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1}} > 0$. Also note that $(1 + \epsilon) < (1 + \epsilon_2)$.

Hence, marginal propensity to consume (MPC) is equal to

$$\begin{aligned} MPC &= \frac{s(1 + \epsilon_2)}{\left\{1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1}\right\} \times s \times (1 + \epsilon)} \\ &= \frac{s(1 + \epsilon_2)}{\left\{1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1}\right\} \times s} \times \frac{1 - \frac{(1+s)\eta}{\epsilon_1} + s \frac{\epsilon_2}{\epsilon_1}}{(1 + \epsilon_2) \left(1 - \frac{(1+s)\eta}{\epsilon_1}\right)} \\ &= \frac{1}{1 - \frac{(1+s)\eta}{\epsilon_1}} > 0 \end{aligned}$$

In the case of quasi-linear utility, $\epsilon_1 = -\infty$ and $MPC = 1$.

General equilibrium

In the general equilibrium version of the model, we consider two sectors. The first sector (sector A) produces consumer goods. The second sector (sector B) produces gasoline. Gasoline is consumed by households working in both sectors. Gasoline is also a production input in the first sector. We assume that households cannot move across sectors, which is likely a reasonable approximation in the short-to-medium run. The mass of households in sector A is q . The mass of households in sector B is $1 - q$. The economy is closed.

Households in sector A solve the following maximization problem:

$$\begin{aligned} \max & m(c_1^A) + u(c_2^A) - v(L^A) \\ \text{s. t.} & c_1^A + p_2 c_2^A = w^A L^A \end{aligned}$$

where c_1 is the numeraire good (or “non-gasoline spending”; we normalize $p_1 = 1$), c_2 is “gasoline”, L is labor, w is wages. After log-linearization of first-order conditions and the budget constraint, we have

$$\begin{aligned}\check{c}_1^A &= \epsilon_1^A \check{\lambda}^A \\ \check{c}_2^A &= \epsilon_2^A (\check{\lambda}^A + \check{p}_2) \\ \frac{v''(L)L}{v'(L)} \check{L}^A &= \eta^{A-1} \check{L}^A = \check{\lambda}^A + \check{w}^A \\ \check{c}_1^A &= \frac{w^A L^A}{c_1^A} (\check{L}^A + \check{w}^A) - \frac{p_2 c_2^A}{c_1^A} (\check{p}_2 + \check{c}_2^A) = (1 + s^A) (\check{L}^A + \check{w}^A) - s^A (\check{p}_2 + \check{c}_2^A)\end{aligned}$$

where $s^A \equiv \frac{p_2 c_2^A}{c_1^A}$ and $\frac{w^A L^A}{c_1^A} = \frac{c_1^A + p_2 c_2^A}{c_1^A} = 1 + s^A$ and $\eta^A = \left(\frac{v''(L)L}{v'(L)}\right)^{-1}$ is the Frisch labor supply elasticity, $\epsilon_2^A \equiv \frac{u'(c_2)}{u''(c_2)c_2} < 0$ and $\epsilon_1^A \equiv \frac{m'(c_1)}{m''(c_1)c_1} < 0$. Note that the first two conditions imply that $\check{c}_2^A = \frac{\epsilon_2^A}{\epsilon_1^A} \check{c}_1^A + \epsilon_2^A \check{p}_2$.

Households in sector B solve the following maximization problem:

$$\begin{aligned}\max & m(c_1^B) + u(c_2^B) - v(L^B) \\ \text{s. t.} & c_1^B + p_2 c_2^B = w^B L^B\end{aligned}$$

After log-linearization of first-order conditions and the budget constraint, we have

$$\begin{aligned}\check{c}_1^B &= \epsilon_1^B \check{\lambda}^B \\ \check{c}_2^B &= \epsilon_2^B (\check{\lambda}^B + \check{p}_2) \\ \frac{v''(L)L}{v'(L)} \check{L}^B &= \eta^{B-1} \check{L}^B = \check{\lambda}^B + \check{w}^B \\ \check{c}_1^B &= \frac{w^B L^B}{c_1^B} (\check{L}^B + \check{w}^B) - \frac{p_2 c_2^B}{c_1^B} (\check{p}_2 + \check{c}_2^B) = (1 + s^B) (\check{L}^B + \check{w}^B) - s^B (\check{p}_2 + \check{c}_2^B)\end{aligned}$$

where $s^B \equiv \frac{p_2 c_2^B}{c_1^B}$ and $\frac{w^B L^B}{c_1^B} = \frac{c_1^B + p_2 c_2^B}{c_1^B} = 1 + s^B$ and $\eta^B = \left(\frac{v''(L)L}{v'(L)}\right)^{-1}$ is the Frisch labor supply elasticity, $\epsilon_2^B \equiv \frac{u'(c_2)}{u''(c_2)c_2} < 0$ and $\epsilon_1^B \equiv \frac{m'(c_1)}{m''(c_1)c_1} < 0$. Note that the first two conditions imply that $\check{c}_2^B = \frac{\epsilon_2^B}{\epsilon_1^B} \check{c}_1^B + \epsilon_2^B \check{p}_2$.

Production in sector A is characterized by constant return to scale and perfect competition:

$$Y_1 = (L^A)^\alpha O^{1-\alpha} \Rightarrow \check{Y}_1 = \alpha \check{L}^A + (1 - \alpha) \check{O}$$

where O is gasoline used in production of good 1. Perfect competition means $p_1 = MC_1$. Given normalization $p_1 = 1$, we have $MC_1 = 1$. Given the Cobb-Douglas production function, we find that $\check{MC} = \alpha \check{w}^A + (1 - \alpha) \check{p}_2$. This means that

$$\check{w}^A = -\left(\frac{1 - \alpha}{\alpha}\right) \check{p}_2.$$

Production in sector B is also characterized by constant return to scale (production function is linear in labor) and perfect competition:

$$Y_2 = L^B \Rightarrow \check{Y}_2 = \check{L}^B$$

$$w^B = MPL = MC = p_2 \Rightarrow \check{w}^B = \check{p}_2$$

Market clearing in sector A:

$$Y_1 = qc_1^A + (1-q)c_1^B \Rightarrow \check{Y}_1 = \left(\frac{qc_1^A}{Y_1}\right)\check{c}_1^A + \left(\frac{(1-q)c_1^B}{Y_1}\right)\check{c}_1^B$$

Market clearing in sector B:

$$Y_2 = qc_2^A + (1-q)c_2^B + qO \Rightarrow \check{Y}_2 = \left(\frac{qc_2^A}{Y_2}\right)\check{c}_2^A + \left(\frac{(1-q)c_2^B}{Y_2}\right)\check{c}_2^B + \left(\frac{qO}{Y_2}\right)\check{O}$$

where qO is the total amount of oil consumed in production of good 1 (each firm in this sector consumes O and q is the mass of firms in the sector).

Now we derive MPC for each group of households:

$$\check{c}_1^A = -\frac{(1+s^A)(1+\eta_A)\left(\frac{1-\alpha}{\alpha}\right) + s^A(1+\epsilon_2^A)}{1 - \frac{(1+s^A)\eta^A}{\epsilon_1^A} + \frac{s^A\epsilon_2^A}{\epsilon_1^A}}\check{p}_2$$

Clearly, $\frac{\partial \check{c}_1^A}{\partial \check{p}_2} < 0$.

$$\check{L}_A = \eta(\check{\lambda}^A + \check{w}^A) = -\eta \times \frac{\left(\frac{1-\alpha}{\alpha}\right)(1+\epsilon_1^A) - \frac{s^A}{\alpha}(1+\epsilon_2^A)}{\epsilon_1^A - (1+s^A)\eta^A + s^A\epsilon_2^A}\check{p}_2$$

We can generate $\frac{\partial \check{L}_A}{\partial \check{p}_2} < 0$ if demand for good “1” is sufficiently elastic (i.e., $\epsilon_1^A < -1$), which seems a reasonable assumption. With utility quasi-linear c_1 , we have $\check{L}_A = -\eta\left(\frac{1-\alpha}{\alpha}\right)\check{p}_2$.

The sensitivity of group A’s total spending on gasoline to the price of gasoline is

$$\check{p}_2 + \check{c}_2^A = \frac{(1+\epsilon_2^A)\epsilon_1^A - \epsilon_2^A(1+s)\left(\frac{1-\alpha}{\alpha}\right) - (1+s)\eta^A\left(1+\frac{\epsilon_2^A}{\alpha}\right)}{\epsilon_1^A - (1+s^A)\eta^A + s^A\epsilon_2^A}\check{p}_2$$

$$\text{Hence, } (1+\epsilon^A) = \frac{(1+\epsilon_2^A)\epsilon_1^A - \epsilon_2^A(1+s)\left(\frac{1-\alpha}{\alpha}\right) - (1+s)\eta^A\left(1+\frac{\epsilon_2^A}{\alpha}\right)}{\epsilon_1^A - (1+s^A)\eta^A + s^A\epsilon_2^A}.$$

The MPC we define in the paper is

$$\begin{aligned}\check{c}_1^A &= -\frac{(1+s^A)(1+\eta_A)\left(\frac{1-\alpha}{\alpha}\right) + s^A(1+\epsilon_2^A)}{1 - \frac{(1+s^A)\eta^A}{\epsilon_1^A} + \frac{s^A\epsilon_2^A}{\epsilon_1^A}} \check{p}_2 \\ &= -\frac{(1+s^A)(1+\eta_A)\left(\frac{1-\alpha}{\alpha}\right) + s^A(1+\epsilon_2^A)}{1 - \frac{(1+s^A)\eta^A}{\epsilon_1^A} + \frac{s^A\epsilon_2^A}{\epsilon_1^A}} \times \frac{1}{(1+\epsilon^A)} \times \frac{1}{s^A} \times s^A \times (1+\epsilon^A) \times \check{p}_2\end{aligned}$$

That is,

$$\begin{aligned}MPC^A &= \frac{(1+s^A)(1+\eta_A)\left(\frac{1-\alpha}{\alpha}\right) + s^A(1+\epsilon_2^A)}{1 - \frac{(1+s^A)\eta^A}{\epsilon_1^A} + \frac{s^A\epsilon_2^A}{\epsilon_1^A}} \times \frac{1}{(1+\epsilon^A)} \times \frac{1}{s^A} \\ &= \frac{1 + \frac{(1+s^A)(1+\eta_A)}{s^A} \left(\frac{1-\alpha}{1+\epsilon_2^A}\right)}{1 - \frac{\epsilon_2^A}{\epsilon_1^A} \times \frac{(1+s^A)}{(1+\epsilon_2^A)} \times \frac{1-\alpha+\eta}{\alpha} - \frac{(1+s^A)\eta}{(1+\epsilon_2^A)\epsilon_1^A}} \\ &= \frac{1 + \frac{(1+s^A)(1+\eta_A)}{s^A} \left(\frac{1-\alpha}{1+\epsilon_2^A}\right)}{1 - \frac{\eta^A(1+s^A)}{\epsilon_1^A} - \frac{\epsilon_2^A}{\epsilon_1^A} \times \frac{(1+s^A)}{(1+\epsilon_2^A)} \times \frac{1-\alpha}{\alpha}}\end{aligned}$$

For comparison, in the partial equilibrium model (effectively $\alpha = 1$) we had

$$MPC = \frac{1}{1 - \frac{(1+s)\eta}{\epsilon_1}} < 1$$

Note that the general equilibrium MPC for this group is greater than the partial equilibrium MPC because $\frac{(1+s^A)(1+\eta_A)}{s^A} \left(\frac{1-\alpha}{1+\epsilon_2^A}\right) > 0$ and $\frac{\epsilon_2^A}{\epsilon_1^A} \times \frac{(1+s^A)}{(1+\epsilon_2^A)} \times \frac{1-\alpha}{\alpha} > 0$ (provided $\epsilon_2^A > -1$).

Doing a similar derivation for group B, we find that

$$\check{c}_1^B = \frac{(1+s^B)(1+\eta_B) - s^B(1+\epsilon_2^B)}{\epsilon_1^B - (1+s^B)\eta^B + s^B\epsilon_2^B} \epsilon_1^B \check{p}_2$$

Note that \check{c}_1^B increases in \check{p}_2 .

Employment for these agents increases in response to a shock in p_2 if their demand for good “1” is sufficiently elastic:

$$\check{L}^B = \eta \frac{1 + \epsilon_1^B}{\epsilon_1^B - (1+s^B)\eta^B + s^B\epsilon_2^B} \check{p}_2$$

With utility quasi-linear in c_1 (i.e., $\epsilon_1^B = -\infty$), we have $\check{L}^B = \eta^B \check{p}_2$.

Now the sensitivity of group B’s total spending on gasoline to the price of gasoline is

$$\begin{aligned}
\check{p}_2 + \check{c}_2^B &= \check{p}_2 + \frac{\epsilon_2^B}{\epsilon_1^B} \check{c}_1^B + \epsilon_2^B \check{p}_2 \\
&= (1 + \epsilon_2^B) \check{p}_2 - \frac{\epsilon_2^B (1 + s^B)(1 + \eta^B) - s^B (1 + \epsilon_2^B)}{\epsilon_1^B \epsilon_1^B - (1 + s^B)\eta^B + s^B \epsilon_2^B} \epsilon_1^B \check{p}_2 \\
&= (1 + \epsilon_2^B) \left\{ \frac{\epsilon_1^B - (1 + s^B)\eta^B + \frac{\epsilon_2^B (1 + s^B)(1 + \eta^B)}{(1 + \epsilon_2^B)}}{\epsilon_1^B - (1 + s^B)\eta^B + s^B \epsilon_2^B} \right\} \check{p}_2
\end{aligned}$$

Hence,

$$(1 + \epsilon^B) = (1 + \epsilon_2^B) \left\{ \frac{\epsilon_1^B - (1 + s^B)\eta^B + \frac{\epsilon_2^B (1 + s^B)(1 + \eta^B)}{(1 + \epsilon_2^B)}}{\epsilon_1^B - (1 + s^B)\eta^B + s^B \epsilon_2^B} \right\} > (1 + \epsilon_2^B)$$

It follows that MPC for type B is

$$MPC^B = - \frac{\left(\frac{1 + s^B}{s^B}\right) \left(\frac{1 + \eta^B}{1 + \epsilon_2^B}\right) - 1}{1 - (1 + s^B) \frac{\eta^B}{\epsilon_1^B} + \left(\frac{\epsilon_2^B}{\epsilon_1^B}\right) \frac{(1 + s^B)(1 + \eta^B)}{(1 + \epsilon_2^B)}}$$

The denominator is positive ($\epsilon_2^B > -1$). The numerator is positive too ($\epsilon_2^B > -1$). Thus, this MPC is negative and can be greater than one in absolute magnitude. For example, with infinitely elastic demand for good “1” (i.e., quasi-linear utility in c_1), we have

$$MPC^B = - \left\{ \left(\frac{1 + s^B}{s^B}\right) \left(\frac{1 + \eta^B}{1 + \epsilon_2^B}\right) - 1 \right\} < 0$$

which can be less than -1 provided that the share good “2” in the consumption basket of type B agent (s^B) is sufficiently small.

The aggregate employment depends on the relative strength of employment responses across sectors:

$$\check{L} = q\check{L}^A + (1 - q)\check{L}^B$$

For the case with quasi-linear utility, we have $\check{L}_A = -\eta^A \left(\frac{1-\alpha}{\alpha}\right) \check{p}_2$ and $\check{L}^B = \eta^B \check{p}_2$. Output is likely to decrease in response to a hike in oil prices. First, one can proxy inelastic supply of gasoline with inelastic supply of labor, that is $\eta^B \approx 0$ and hence \check{L}_A (which has a clear sign) drives aggregate employment. Second, $1 - q$ is small and, thus, it would take very large employment effects in sector 2 to drive aggregate employment.

The aggregate $\overline{MPC} = qMPC^A + (1 - q)MPC^B$. Note that MPC^A and MPC^B have different signs. Depending on parameter values, partial equilibrium MPC can be greater or smaller than the aggregate \overline{MPC} .
