Abstract: We consider two semiparametric models for the weight function in a biased sample model. The object of our interest parametrizes the weight function, and it is either Euclidean or non Euclidean. One of the models discussed in this paper is motivated by the estimation the mixing distribution of individual utility functions in the DAX market.

## 1. Introduction

A sample $X_{1}, \ldots, X_{n}$ is considered biased if it is sampled from a density $p$ which is represented as

$$
\begin{equation*}
p(x)=\frac{q(x) w(x)}{\int q(u) w(u) d u} \tag{1}
\end{equation*}
$$

Here $q$ is some 'natural' pdf (probability density function) for the problem, representing the 'true' underlying distribution, while $w$ is a given weight function that biases the sample. In a standard example, $X$ represents the severity of the disease, and $q$ is the density of $X$ among patients at admission to the hospital. However, it may be more convenient to take a random sample from the population of patients who are in the hospital at a given time. If the time of hospitalization is proportional to the severity of the case, then the sample is taken from the density $p$, which is equal to $q$ 'length biased' with $w(x) \equiv x$. Vardi (1985) was the first to analyze systematically these type of models. Asymptotic theory was develop in Gill, Vardi and Wellner (1988). Gilbert, Lele, and Vardi (1999) extended the model to the situation where the weight function depends on some parameter, $w(x)=w(x ; f)$. The large sample properties were discussed in Gilbert (2000).

Our paper is about estimating $f$, the parameter of the weight function, $w(x)=$ $w(x ; f)$. Two semiparametric models are discussed in this paper. The first model is an experimental design problem in which the concept of biased sample is introduced in a situation where a direct sample is in fact impossible. The model for $q$ is semiparametric, while the parameter of interest, $f$, is Euclidean. In the second model we consider, $q$ is taken as known, while the weight function is parametrized by a non-Euclidean parameter. This brings us to an inverse problem of estimating and demixing the weight.

The purpose of the first model is to design an experiment in order to evaluate the relative attractiveness of different baits. See for example Ji, Veitch, and Craig (1999). It can be described as follows. Suppose that traps are distributed with different baits. We do not know much about the animal population. We do not know even how many animals visited each trap. We know only the number and characteristics of the animals who were tempted by each of the baits and were captured. For simplicity we assume that each trap and bait can attract and catch unlimited number of animals. We want to estimate the attractiveness of each type of bait as a function of the animal characteristics, and do that from the sample in which a datum is a pair of an animal and a bait.

The second model is motivated by research on risk aversion and proclivity, more precisely on the empirical pricing kernel (EPK). See Detlefsen, Härdle and Moro (2007) (hereafter DHM). The EPK describes the apparent utility behavior as function of individual investors utility function.

In this model $q$ is the risk neutral density of assets pricing. It is derived from theoretical considerations. The density $p$ on the other hand is the empirical (historical) prices. See Figure 1 (a) and (b) for an example. In asset pricing the

EPK links risk neutral investor's behavior to individual utilities, which gives in our notation a semiparametric modeling of the weight function $w$. The integral function of the pricing kernel $q / p$ is the utility function used by a representing individual. Knowing $p$ and $q$ yields the exact form of the utility function, cf. Ait-Sahalia and Lo (2000). The risk neutral (state price) density (SPD) $q$ can be calculated from the market data on European options, in the DAX data-set. There are more than 5000 observations each day for maturity from 1 week to 2 years. The SPD can therefore be estimated very precisely. Much empirical research work has demonstrated the so called EPK paradox: The resulting utility function is partially concave and partially convex, more precisely of the Friedman and Savage type. See Friedman and Savage (1948).

It is assumed in DHM that the observed density of the DAX value has density of the form $p(x)=c q(x) w(x ; f)$ where $q \in\left\{q_{\nu}, \nu \in N \subseteq \mathbb{R}^{d}\right\}$ is theoretical derived risk neutral density, assumed to follow a given parametric function and $c$ is a normalization factor. That is, of the type of equation (1). The weight function is theoretically derived to be given by $1 / U^{\prime}(x)$, where $U$ is the market utility function, and prime denotes derivative. The market utility function itself is assumed to be a function of the mixture of the individual investors:

$$
x=U^{-1}(u)=\int g(u ; \xi) f(\xi) d \xi
$$

Here $\xi$ denotes an investor type, $f$ is the density of the investors' distribution, and the function $g(\cdot ; \cdot)$ is the inverse utility function and it is considered known. A subject of type $\xi$ has the inverse utility function $g(\cdot ; \xi)$, or equivalently, the utility function $u(\cdot ; \xi)$ satisfying $g\{u(x ; \xi) ; \xi\} \equiv x$. The problem we consider in this paper is to find the density $f$. We obtain the representation:

$$
\begin{equation*}
p(x)=c q(x) \int \frac{\partial}{\partial u} g(u ; \xi) f(\xi) d \xi, \quad \text { with } x=\int g(u ; \xi) f(\xi) d \xi \tag{2}
\end{equation*}
$$

See Figure 1 for an example taken from DHM of estimates of $p, q$, and $f$.
We will investigate the estimation rate for a few utility functions. The result is typical for inverse problems, in that slightly different assumption will yield completely different results. In fact, we will present three similar models, similar to those investigated in DHM, that exhibit three different type of behavior:
(i) There is no consistent estimator of $f$;
(ii) $f$ can be estimated at a regular nonparametric rate of $n^{-\alpha}$;
(iii) $f$ can be estimated but at a very slow rate.

We will also show a sort of uncertainty principle. The better we can estimate the function $U^{-1}(u)$, the worse we can demix it and estimate $f$. This is reasonable. We cannot estimate $f$ well, when large differences in $f$ have only minor impact on $\int g(\cdot ; \xi) f(\xi) d \xi$.

There are two unified themes to the paper. The first is the usefulness of the concept of biased sample of unknown weight function, even in models where this point of view is not automatic. The second is the technical analysis of inverse problem which starts with a naive estimator that not much is known

[^1]

Fig 1: The DAX data, 24/03/2000 half a year look ahead: (a) $p$, the historical density; (b) $q$, the risk neutral density; (c) The estimate of $f$, the mixing density. Figures are taken from DHM
about it, and then improving it. The structure of the rest of the paper is as follows. In Section 2 we consider a parametric model for the weight function, and show the simplicity of the result. Then, in Section 3 , we suggest an algorithm for calculating the generalized maximum-likelihood estimator (GMLE) for the semiparametric weight function of the model suggested by DHM. Finally rates of convergence of the demixing estimator for the DHM's model are discussed in Section 4 , as well as of estimates of the mixture itself.

## 2. The parametric bait problem

Animals of type $z$ are trapped by a bait of type $u$ with probability which is proportional to $w(z, u ; f)$. We do know about the animals only after they are caught by the traps. Our aim is to design an experiment and to estimate $f$. The solution in a nutshell is to distribute many different baits and compare the difference between the animals captured by the different baits, somewhat similar to what is done in case-control studies.

Let $X=(U, Z)$ where $U$ denotes the bait property (e.g., percentage of fat) and $Z$ is a vector of measurement for each animal (e.g., gender, weight, and age). Baits with known (designed!) distribution $g$ are spread, and are encountered by the animals. We assume therefore that the data is sampled from the joint density given by

$$
\begin{equation*}
p(u, z)=\frac{w(u, z ; f) g(u) h(z)}{\iint w(\tilde{u}, \tilde{z} ; f) g(\tilde{u}) h(\tilde{z}) \mu(\tilde{u}) d \nu(\tilde{z})} \tag{3}
\end{equation*}
$$

with respect to the product measure $\mu \times \nu$, and where $w(u, z ; f)$ is some parametric weight function, for example, if $u$ is a scalar and $z \in \mathbb{R}^{d}$, we can consider

$$
\begin{equation*}
w(u, z ; f)=\exp \left\{u f^{\top} z\right\} \tag{4}
\end{equation*}
$$

Our aim is to estimate $f$. The density $h$ is an unknown distribution over $\mathbb{R}^{d}, d$ large.

Suppose we consider the weight function (4), then the likelihood equation for $f$ is

$$
0=\sum U_{i} Z_{i}-n \frac{\iint u z e^{u f^{\top} z} g(u) h(z) d \mu(u) d \nu(z)}{\iint e^{u f^{\top} z} g(u) h(z) d \mu(u) d \nu(z)}
$$

Assuming that $Z$ has at least one Lebesgue continuous component, the GMLE (generalized maximum likelihood estimator) of its distribution is discrete with a point mass at each observation, so that we obtain

$$
0=\sum_{i=1}^{n} U_{i} Z_{i}-n \frac{\sum_{j} \int u z_{j} e^{u \boldsymbol{\top}^{\top} z_{j}} g(u) \hat{h}_{j} d \mu(u)}{\sum_{j} \int e^{u f^{\top} \boldsymbol{\tau}_{z_{j}}} g(u) \hat{h}_{j} d \mu(u)}
$$

where $\hat{h}_{j}$ is the estimated mass at the point $Z_{j}$. However, the likelihood equation for $h$ is

$$
0=\frac{1}{\hat{h}_{j}}-n \frac{\int e^{u f^{\top} Z_{j}} g(u) d \mu(u)}{\sum_{i=1}^{n} \int e^{u f^{\top} Z_{i}} g(u) d \mu(u) \hat{h}_{i}}
$$

Plugging this into the profiled log-likelihood equation for $f$ we obtain

$$
\begin{aligned}
0=\frac{1}{n} \dot{\ell}(f) & =\frac{1}{n} \sum_{i=1}^{n} U_{i} Z_{i}-\sum_{j=1}^{n} \frac{\int u z_{j} e^{u f^{\top} z_{j}} g(u) d \mu(u)}{\int e^{u f^{\top} z_{j}} g(u) d \mu(u)} \\
& =\frac{1}{n} \sum_{i=1}^{n} Z_{i}\left\{U_{i}-\mathrm{E}_{f}\left(U \mid f^{\top} Z_{i}\right)\right\} \\
& =\frac{1}{n} \sum_{i=1}^{n} T\left(U_{i}, Z_{i} ; f\right), \quad \text { say } .
\end{aligned}
$$

For example, in the simple case where $g$ is uniform on the interval $(a, b)$ :

$$
\mathrm{E}_{f}(U \mid z)=\frac{\int_{a}^{b} u e^{u f^{\top} z} d z}{\int_{a}^{b} e^{u f^{\top} z} d u}=\frac{b e^{b f^{\top} u}-a e^{a f^{\top} \mathrm{\top}_{z}}}{e^{b f^{\top} \tau_{z}}-e^{a f^{\top} \mathrm{\top}_{z}}}-\frac{1}{f^{\top} z}
$$

if $f^{\top} z \neq 0$, and $(a+b) / 2$ otherwise.
Generally, the derivative of $\mathrm{E}_{f}\left(U \mid f^{\top} Z_{i}\right)$ is $-\operatorname{Var}_{f}\left(U \mid f^{\top} z\right) Z Z^{\top}$. Hence $\ell$ is concave in $f$. This yields that the maximizer of $\ell$ is simple to find and is asymptotically normal with asymptotic covariance function given by $\mathrm{E}\left\{\operatorname{Var}_{f}\left(U \mid f^{\top} z\right) Z Z^{\top}\right\}$

## 3. EPK: Model and an EM estimator

We consider now the EPK problem. We start now from (2) and we assume that $q$ is known. In practice, it is assumed only to belong to some parametric family
$\left\{q_{\nu}\right\}$. However, we will deal in the following in rates which are slower than the parametric $\sqrt{n}$ rate, and the estimate of $\nu$ is based on much larger sample than the estimates of the rest of the parameters. Therefore, the assumption that $\nu$ is known simplifies the discussion without a real impact on the results.

Rewrite (2) as

$$
\begin{align*}
& p\left\{\int g(u ; \xi) f(\xi) d \mu(\xi)\right\} \int \frac{\partial}{\partial u} g(u ; \xi) f(\xi) d \mu(\xi) \\
& \quad=c q\left\{\int g(u ; \xi) f(\xi) d \mu(\xi)\right\}\left\{\int \frac{\partial}{\partial u} g(u ; \xi) f(\xi) d \mu(\xi)\right\}^{2} \tag{5}
\end{align*}
$$

where $\mu$ is some dominating measure (i.e., the Lebesgue or the counting meausres). Noting that the LHS of (5) is integrated to 1, we can solve for $c$ and obtain

$$
p\left\{\int g(u ; \xi) f(\xi) d \mu(\xi)\right\}=\frac{q\left\{\int g(u ; \xi) f(\xi) d \mu(\xi)\right\} \int \frac{\partial}{\partial u} g(u ; \xi) f(\xi) d \mu(\xi)}{\int q\left\{\int g(v ; \xi) f(\xi) d \mu(\xi)\right\}\left\{\int \frac{\partial}{\partial u} g(v ; \xi) f(\xi) d \mu(\xi)\right\}^{2} d v}
$$

The market utility $U(x)=U(x ; f)$ is given by

$$
x \equiv \int g\{U(x ; f) ; \xi\} f(\xi) d \mu(\xi) \equiv \psi_{f}\{U(x ; f)\} .
$$

We obtain

$$
\begin{align*}
p(x) & =\frac{q(x) \int \frac{\partial}{\partial u} g(U(x ; f) ; \xi) f(\xi) d \mu(\xi)}{\int q(y) \int \frac{\partial}{\partial u} g(U(y ; f) ; \xi) f(\xi) d \mu(\xi) d y} \\
& =\frac{q(x) \psi_{f}^{\prime}\left\{\psi_{f}^{-1}(x)\right\}}{\int q(y) \psi_{f}^{\prime}\left\{\psi_{f}^{-1}(y)\right\} d y} . \tag{6}
\end{align*}
$$

The statistical model assumed by DHM is that we obtain a simple random sample from $p$, where $p$ is parametrized in (6) by the non-Euclidean parameter $f$. A natural approach is to estimate $f$ by the MLE or a variant of it, which we develop now. Note that $\nabla_{f} \psi_{f}(u)=g(u ; \cdot)$, and by taking the gradient of $x \equiv \int g\left\{\psi_{f}^{-1}(x) ; \xi\right\} f(\xi) d \mu(\xi)$ we obtain

$$
0=g\left\{\psi_{f}^{-1}(x) ; \cdot\right\}+\psi_{f}^{\prime}\left\{\psi_{f}^{-1}(x)\right\} \nabla_{f} \psi_{f}^{-1}(x)
$$

The derivative of the log-likelihood is given therefore by

$$
\begin{aligned}
\dot{\ell}_{f}(\xi)= & \sum_{i=1}^{n} \frac{1}{\psi_{f}^{\prime}\left\{\psi_{f}^{-1}\left(X_{i}\right)\right\}}\left[\frac{\partial}{\partial u} g\left\{\psi_{f}^{-1}\left(X_{i}\right) ; \xi\right\}-\frac{\psi_{f}^{\prime \prime}}{\psi_{f}^{\prime}}\left\{\psi_{f}^{-1}\left(X_{i}\right)\right\} g\left\{\psi_{f}^{-1}\left(X_{i}\right) ; \xi\right\}\right] \\
& \quad-n A_{f}(\xi), \quad \xi \in \operatorname{supp} f \\
= & \sum_{i=1}^{n} \frac{1}{\psi_{f}^{\prime}\left\{U_{i}\right\}}\left\{\frac{\partial}{\partial u} g\left\{U_{i} ; \xi\right\}-\frac{\psi_{f}^{\prime \prime}}{\psi_{f}^{\prime}}\left(U_{i}\right) g\left(U_{i} ; \xi\right)\right\}-n A_{f}(\xi), \\
& U_{i}=\psi_{f}^{-1}\left(X_{i}\right), \quad \xi \in \operatorname{supp} f,
\end{aligned} \text { imsart-generic ver. 2007/02/20 file: biasedSample.tex date: May 1, } 2007
$$

where $A_{f}(\xi)$ is the mean of the first term under $f$. Since the density of $U_{i}$ is given by

$$
r_{f}(u)=p\left\{\psi_{f}(u)\right\} \psi_{f}^{\prime}(u)=\frac{q\left\{\psi_{f}(u)\right\}\left\{\psi_{f}^{\prime}(u)\right\}^{2}}{\int q\left\{\psi_{f}(v)\right\}\left\{\psi_{f}^{\prime}(v)\right\}^{2} d v}
$$

We obtain that

$$
A_{f}(\xi)=\frac{\int q\left\{\psi_{f}(u)\right\}\left\{\psi_{f}^{\prime}(u) \frac{\partial}{\partial u} g(u ; \xi)-\psi_{f}^{\prime \prime}(u) g(u ; \xi)\right\} d u}{\int q\left\{\psi_{f}(v)\right\}\left\{\psi_{f}^{\prime}(v)\right\}^{2} d v}
$$

The model of random sample from the density $p$ can be well approximated as $\sigma \rightarrow 0$ by a $X_{i}=\psi_{f}\left(U_{i}\right)+\varepsilon_{i}, i=1, \ldots, n$, where $\varepsilon_{1}, \ldots, \varepsilon_{n}$ is a random sample from $N\left(0, \sigma^{2}\right)$ independent from the random sample $U_{1}, \ldots, U_{n}$ taken from the density $r_{f}$. Now, the log-likelihood of the joint density is given by

$$
\ell_{f}=\sum_{i=1}^{n}\left[\log q\left\{\psi_{f}\left(U_{i}\right)\right\}+2 \log \left\{\psi_{f}^{\prime}\left(U_{i}\right)\right\}\right]-n C_{f}-\frac{1}{2 \sigma^{2}} \sum_{i=1}^{n}\left(X_{i}-\psi_{f}\left(U_{i}\right)\right)^{2}
$$

where

$$
C_{f}=\log \int q\left\{\psi_{f}(v)\right\}\left\{\psi_{f}^{\prime}(v)\right\}^{2} d v
$$

By a well known formula for the Bayes estimator in the Gaussian measurement error model, under the above model, the distribution of $\psi_{f}\left(U_{i}\right)-X_{i}$ given $X_{i}$ is normal with mean $\sigma^{2} f_{X}^{\prime}\left(X_{i}\right) / f_{X}\left(X_{i}\right)$ and a second moment equal to $\sigma^{4} f_{X}^{\prime \prime}\left(X_{i}\right) / f_{X}\left(X_{i}\right)+\sigma^{2}$, where $f_{X}$ is the marginal density of $X_{i}$. At the limit as $\sigma^{2} \rightarrow 0$, the conditional expectation of the log-likelihood given the $X_{i} \mathrm{~s}$ amounts therefore to replacing $U_{i}$ by $\psi_{f}^{-1}\left(X_{i}\right)$. We conclude that the limiting EM algorithm iterates therefore between

$$
\text { The E step: } \quad U_{i} \leftarrow \psi_{f}^{-1}\left(X_{i}\right), \quad i=1, \ldots, n
$$

and

$$
\text { The M step: } f \leftarrow \arg \max \left[\sum_{i=1}^{n}\left\{\log q\left\{\psi_{f}\left(U_{i}\right)\right\}+2 \log \left\{\psi_{f}^{\prime}\left(U_{i}\right)\right\}\right\}-n C_{f}\right] \text {. }
$$

Let $\mathbf{U}=\left(U_{1}, \ldots, U_{n}\right), \mathbf{X}=\left(X_{1}, \ldots, X_{n}\right)$, and denote the E-step by $\mathbf{U}=$ $\psi_{f}^{-1}(\mathbf{X})$. The M-step can be solved by solving the likelihood equation:

$$
\begin{align*}
0 & =\dot{\ell}_{f}^{M}(\xi ; \mathbf{U}) \\
& =\sum_{i=1}^{n}\left[\frac{q^{\prime}\left\{\psi_{f}\left(U_{i}\right)\right\}}{q\left\{\psi_{f}\left(U_{i}\right)\right\}} g\left(U_{i} ; \xi\right)+\frac{2}{\psi_{f}^{\prime}\left(U_{i}\right)} \frac{\partial}{\partial u} g\left(U_{i}, \xi\right)-\dot{C}_{f}(\xi)\right], \tag{7}
\end{align*}
$$

for all $\xi \in \operatorname{supp} f$, where

$$
\begin{aligned}
\dot{C}_{f}(\xi) & =\frac{\int\left[\frac{q^{\prime}\left\{\psi_{f}(v)\right\}}{q\left\{\psi_{f}(v)\right\}} g(v ; \xi)+\frac{2}{\psi_{f}^{\prime}(v)} \frac{\partial}{\partial u} g(v, \xi)\right] q\left\{\psi_{f}(v)\right\}\left\{\psi_{f}^{\prime}(v)\right\}^{2} d v}{\int q\left\{\psi_{f}(v)\right\}\left\{\psi_{f}^{\prime}(v)\right\}^{2} d v} \\
& =\mathrm{E}_{f}\left[\frac{q^{\prime}\left\{\psi_{f}(U)\right\}}{q\left\{\psi_{f}(U)\right\}} g(U ; \xi)+\frac{2}{\psi_{f}^{\prime}(U)} \frac{\partial}{\partial u} g(U, \xi)\right] \\
& =\mathrm{E}_{f}\left\{T_{f}(U ; \xi)\right\}, \quad \text { say } .
\end{aligned}
$$

An approximate M-step (which is enough, since all we need in the M-step is that the likelihood will be strictly increased) is obtained by considering an approximate Newton-Raphson solution of (7), where $\mathcal{O}_{p}(\sqrt{n})$ terms in the Hessian of the log-likelihood are discarded. That is the term

$$
\sum_{i=1}^{n}\left\{\nabla_{f} T_{f}\left(U_{i} ; \xi\right)-\mathrm{E}_{f} \nabla_{f} T_{f}(U ; \xi)\right\}
$$

We consider therefore the algorithm:

$$
f_{i+1}=f_{i}+H_{f_{i}}^{-1} \ell_{f_{i}}^{M}\left\{\cdot ; \psi_{f_{i}}^{-1}(\mathbf{X})\right\}, \quad i=1,2, \ldots,
$$

where $H_{f}: L_{2}(\mu) \rightarrow L_{2}(\mu)$ is the operator given by:

$$
H_{f}(\xi, \zeta)=\operatorname{cov}_{f}\left\{T_{f}(U ; \xi), T_{f}(U ; \zeta)\right\} .
$$

## 4. EPK: Rates of convergence

In the previous section we considered the MLE estimate of $f$. In this section we consider simple estimators of the type suggested by DHM. Using these estimators we will be able to discuss possible minimax rates of convergence. In essence, we start with some naive nonparametric estimator and improve it or demix it for $f$. One simple method for demixing the EPK is to start with (2) which can be written as

$$
\begin{aligned}
1 & =c \int \frac{\partial}{\partial u} g(u ; \xi) f(\xi) d \xi \frac{q}{p}\left\{\int g(u ; \xi) f(\xi) d \xi\right\} \\
& =c \frac{\partial}{\partial u} \frac{q}{p}\left\{\int g(u ; \xi) f(\xi) d \xi\right\}
\end{aligned}
$$

Hence

$$
\frac{q}{p}\left\{\int g(u ; \xi) f(\xi) d \xi\right\}=\alpha+\beta u
$$

for some $\alpha$ and $\beta$, or

$$
\int g(u ; \xi) f(\xi) d \xi=\left(\frac{p}{q}\right)^{-1}(\alpha+\beta u)
$$

The utility function of an individual is defined up to affine transformation. To assure that it is well defined, we assume that that utility at a return of 1 is 0 , and its derivative there is 1 . In other words we assume that $g(0, \xi) \equiv \frac{\partial}{\partial u} g(0, \xi) \equiv 1$. Hence

$$
\begin{aligned}
& \alpha=\frac{p(1)}{q(1)} \\
& \beta=\frac{p^{\prime}(1)}{q(1)}-\frac{p(1)}{q(1)} \frac{q^{\prime}(1)}{q(1)}
\end{aligned}
$$

We therefore want to solve

$$
\begin{equation*}
\int g(u ; \xi) f(\xi) d \xi=\psi(u) \tag{8}
\end{equation*}
$$

for some $\psi$. Since $q$ is estimated as a parametric density (based on a much larger sample), and $p$ can be estimated at a standard non-parametric rate based on a direct sample from $p, \psi$ can as well be estimated at a regular density estimation rate. The analysis of this section starts with (8). We assume that $\psi$ and its relevant derivatives can be estimated in some polynomial rate $\left\|\hat{\psi}^{(i)}-\psi^{i}\right\|_{\infty}=$ $\mathcal{O}_{p}\left(n^{-\alpha_{i}}\right)$ for some $\alpha_{i}>0$. The natural estimator suggested by DHM is given by the inverse function of a weighed density estimator. Under strict monotonicity and boundness, the inverse function inherits most properties from the density kernel estimator.

Note that model (8) looks like a linear model. For example if $f$ is approximated by a finite distribution with point mass at $\xi_{1}, \ldots, \xi_{m}$, and we consider the equation at the $k$ points $u_{1}, \ldots, u_{k}$ then we can write (8) as

$$
\begin{equation*}
\hat{\psi}\left(u_{i}\right)=\sum_{j=1}^{m} \beta_{j} g\left(u_{i} ; \xi_{j}\right)+\varepsilon_{i}, \quad i=1, \ldots, k \tag{9}
\end{equation*}
$$

(9) looks like a standard linear model, and indeed we suggest to estimate $f$ by solving it. However, it is not. Most linear model assumptions are violated. E.g., $\varepsilon_{1}, \ldots, \varepsilon_{k}$ are not i.i.d., they are not independent of the random $u_{1}, \ldots, u_{k}$, which are in fact an estimated function of the observed values $x_{1}, \ldots, x_{k}$.

The basic idea of this section is as follow. We assume that we have some naive nonparametric estimator of $\psi$. We then proceed to use the pseudo linear model (9) to to estimate the mixing distribution and to improve the estimate of $\psi$ itself. We show that this method yields the minimax rates.

How fast can $f$ be estimated? In the rest of the section we present simple examples following DHM. These examples show that in a very similar models very different type of behavior can be obtained. It can be that (i) There is no consistent estimator of $f$; (ii) $f$ can be estimated at a regular nonparametric rate of $n^{-\alpha}$; (iii) $f$ can be estimated but at a very slow rate. Thus one can suspect that any optimistic result of demixing depends too heavily on assumptions, and are a priori not robust (at least in the minimax sense). In particular, any result should be checked to stand against different changes in the model.

### 4.1. Switching between two utilities

Following DHM assume that for $x, \xi>0$ :

$$
\begin{equation*}
U(x ; \xi)=\alpha_{2}(1-c)^{1-1 / \alpha_{2}}\left\{[x-\xi]_{+}^{1 / \alpha_{1}} \vee(x-c)^{1 / \alpha_{2}}\right\}-\alpha_{2}(1-c), \tag{10}
\end{equation*}
$$

where $\alpha_{2}>\alpha_{1}>1$ are given, $c<0$, and $[x]_{+}=x \mathbf{1}(x>0)$. See Figure 2 . Then

$$
g(u ; \xi)=\min \left\{\beta^{\alpha_{2}}\left\{u+\alpha_{2}(1-c)\right\}^{\alpha_{2}}+c, \beta^{\alpha_{1}}\left\{u+\alpha_{2}(1-c)\right\}^{\alpha_{1}}+\xi\right\}
$$

where $\beta=\alpha_{2}^{-1}(1-c)^{-1+1 / \alpha_{2}}$. To simplify and generalize the discussion, we consider the slightly more general case:

$$
g(u ; \xi)=\left\{\begin{array}{ll}
g_{2}(u) & -\infty<u \leq h(\xi) \\
g_{1}(u)+\xi & \infty>u>h(\xi)
\end{array}, \quad \xi>0\right.
$$

where

$$
\begin{equation*}
h^{-1}=g_{2}-g_{1} \tag{11}
\end{equation*}
$$

is a strictly increasing function. Note that $g(u ; \xi)$ is continuous in $\xi$. Then (8) is translated to

$$
\psi(u)=\int^{h^{-1}(u)} \xi f(\xi) d \xi+g_{2}(u) F\left\{h^{-1}(u)\right\}+g_{2}(u)\left\{1-F\left\{h^{-1}(u)\right\}\right\}
$$

where $F$ is the cdf corresponding to the pdf $f$. Changing variables and considering (11)

$$
\psi\{h(s)\}=\int^{s} \xi f(\xi) d \xi-s F(s)+g_{2}\{h(s)\} .
$$

Taking derivative:

$$
F(s)=h^{\prime}(s)\left\{g_{2}^{\prime}\{h(s)\}-\psi^{\prime}\{h(s)\}\right\}
$$

Hence estimating $F$ at $s$ is equivalent to the estimation of $\psi^{\prime}$ at $h(s)$. In other words, $f(\cdot)$ can be estimated at the same rate as the rate of the estimation of second derivative of $\psi$, which in turn is essentially governed by the rate of estimation of the second derivative of $p$, which depends on the level of smoothness assumption we are willing to accept. Thus if we assume that $p$ has $s$ bounded derivatives, then $f$ can be estimated with an $\mathcal{O}_{p}\left(n^{-(s-2) /(2 s+1)}\right)$ error. See Silverman (1986) for a general review of density estimation.

Fig 2: The utility function $U(\cdot ; \xi)$ of (10) $\left(\alpha_{1}=2, \alpha_{2}=2.25, c=2\right)$ for two different values of $\xi$ (solid lines), and of (12) for two values (broken lines).

### 4.2. Polynomial and exponential inverse utility function

The previous example was a relatively optimistic example. However, modest changes in the inverse utility function may create situations in which $f$ can hardly estimated, or even not at all.

Suppose a CRRA (constant relative risk aversion) utility:

$$
g(u ; \zeta)=\left(\alpha \zeta^{\alpha-1}\right)^{-1}\left\{(u+\zeta)^{\alpha}-\zeta^{\alpha}\right\}+1, \quad u \in \mathbb{R}, \zeta \in \mathbb{R}^{+}
$$

where $\alpha$ is known. Note that $g$ is scaled such that both its value and derivative at 0 are equal to 1 . That is, we consider only one branch of (10). If $\alpha$ is an integer, then $\psi(\cdot)$ is a function of only the first $\alpha$ moments of $f$, and hence there is no consistent estimator of $f$.

Seemingly, more and more moments are revealed as $\alpha \rightarrow \infty$. However, it is not clear that they could be estimated effectively. The limiting form of the inverse utility function, as $\alpha \rightarrow \infty$ and $\alpha / \zeta \rightarrow \xi$ is given by

$$
\begin{equation*}
g(u ; \xi) \equiv \xi^{-1}\left(e^{u \xi}-1\right)+1 \tag{12}
\end{equation*}
$$

The density $f$ is now identified. For example, all its moments can be estimated, e.g., by $\int \xi^{i} f(\xi) d \xi=\psi^{(i+1)}(0)$. We are going now to analyze this model in some detail. We will argue now that if $f(\cdot)$ is assumed to have two bounded derivatives, then its value at a point can indeed be estimated, but this can be done only in a very slow convergence rate, slower than any polynomial rate. To be more exact,we argue

Theorem 4.1 Assume that $g$ is given by (12) and $f$ is bounded and has two bounded derivatives. Suppose the minimax rate of estimation of $\psi$ is $n^{\gamma}, \gamma \in(0,1 / 2)$. Then there is an estimator $\hat{f}$ such that $\hat{f}(s)-f(s)=\mathcal{O}_{p}\left(n^{-\alpha \log \log n / \log n}\right)$ for some $\alpha$, and there is no estimator $\tilde{f}(s)$, such that $\tilde{f}(s)-f(s)=\mathcal{O}_{p}\left(n^{-\alpha / \log \log n}\right)$ for some $\alpha$.

The proof is given in Appendix A.

### 4.3. Smoothing the empirical estimate and an uncertainty principle

As in the previous subsections we start with a nonparametric $\hat{\psi}$. The purpose of this subsection is to show that a simple projection of this initial estimator yields a considerably better estimator.

We argued in Subsection 4.2 there that there is no reasonable estimator of $f$ for $g$ given in (12). Is this model useless? The surprising answer is no. Although $f$ cannot be estimated per-se, many of its functionals can be estimated quite easily and quite well. For example, as mentioned, its moments. Similarly $\psi(u)$ considered as a simple linear functional can be estimated quite easily. Suppose that $f$ is supported on some compact interval $[a, b]$. Then one can approximate

$$
\psi(u)=\sum_{i=1}^{m} \beta_{i} u^{i}+R_{m}(u)
$$

where for some $\tilde{u} \in(0, u)$ :

$$
\begin{align*}
0 \leq R_{m}(u) & =\frac{1}{(m+1)!} \psi^{m+1}(\tilde{u}) \\
& =\frac{1}{(m+1)!} \int_{a}^{b} \xi^{m} e^{\tilde{u} \xi} f(\xi) d \xi  \tag{13}\\
& \leq \frac{b^{m} e^{u b}}{(m+1)!} .
\end{align*}
$$

Generally speaking, the faster the coefficients $\beta$ are converging to 0 , the easier it is to estimate $\psi$ and the harder it is to estimate the mixing density $g$. As (13) shows, we need only very few terms to approximate $\psi$ quite well. In fact we show that in this smooth case, where on one hand $f$ can be hardly estimated, $\psi$ can be estimated almost at the parametric rate. This is not an accident - these are two faces of one phenomena. The shape of the observable $\psi$ hardly depends on $f$, and essentially depends only on a few aspects of $f$. These aspects can be estimated well (and hence $\psi$ can be estimated well too). The other aspects can hardly be estimated and hence $f$ cannot be estimated in a reasonable rate. This yields an uncertainty principle - the more you are certain about $\psi$ the less you are about $f$.

Recall that a function $g$ is called completely monotone if $(-1)^{k} g^{(k)} \geq 0$, and it is called Bernstein function if its first derivative is completely monotone. It is well known (Feller, 1996) $g$ is completely monotone if, and only if $g(u)=$

```
imsart-generic ver. 2007/02/20 file: biasedSample.tex date: May 1, 2007
```

$\int_{0}^{\infty} e^{-u \xi} d F(\xi)$. In other words, $\psi$ is a Bernstein function. Nonparametric maximum likelihood estimation for exponential mixture (and hence completely monotone density) was discussed in Jewel (1982). Balabdaoui and Wellner (2007) discussed the estimation of a k-monotone density.

We assume that at our disposal there is an estimate $\hat{\psi}=\hat{\psi}_{n}$. For any $u_{1}, \ldots, u_{k}>$ 0 , let $\Sigma\left(u_{1}, \ldots, u_{k}\right) \in \mathbb{R}^{k \times k}$, where

$$
\Sigma_{i j}\left(u_{1}, \ldots, u_{k}\right)=\operatorname{cov}\left\{\hat{\psi}\left(u_{i}\right), \hat{\psi}\left(u_{j}\right)\right\} .
$$

Consider the following assumption:
A1. For any $n$ there is $k=k_{n}$, and $u_{1}, \ldots, u_{k} \in(c, d), 0<c<d$, such that the spectral radius of $\Sigma\left(u_{1}, \ldots, u_{k}\right)$ is $\mathcal{O}(k / n)$ and $\max _{i}\left|\mathrm{E} \psi\left(u_{i}\right)-\psi\left(u_{i}\right)\right|^{2}=$ $\mathcal{O}(\log n / n)$.

Assumption A1 is satisfied by many nonparametric density and regression estimators when they are strictly under-smooth. We care much more about bias than about variance of the original estimator $\hat{\psi}$. Thus, we have in mind a kernel estimator with bandwidth of order $n^{-1 / 4+\varepsilon}$. The spectral radius is based on the assumptions that the estimator at points that are a multiply of the bandwidth apart are (almost) independent, for example this is trivially the case with kernel estimator with compact support. The relationships in the assumption are derived from assuming that the bias of the estimator is $\mathcal{O}\left(\sigma^{2}\right)$, the variance is $\mathcal{O}(1 / n \sigma)$, and $k=\mathcal{O}\left(\sigma^{-1}\right)$.

Consider now the least squares regression of $Y=\left\{\hat{\psi}\left(u_{1}\right), \ldots, \hat{\psi}\left(u_{k}\right)\right\}^{\top}$ on the design matrix $Z \in \mathbb{R}^{k \times m}, Z_{i j}=u_{i}^{j}$. That is $\hat{\beta}=\left(Z^{\prime} Z\right)^{-1} Z^{\prime} Y$, where $\hat{\beta} \in \mathbb{R}^{m}$. Finally let $\tilde{\psi}(u)=\sum_{j=1}^{m} \hat{\beta}_{j} u^{j}, u>0$. We argue that the error achieved by $\tilde{\psi}$ is almost the parametric rate even although $\hat{\beta}$ achieves can be estimated in strictly lower rate.

Theorem 4.2 Suppose $g(u ; \xi) \equiv \xi^{-1}\left(e^{u \xi}-1\right)$ and that $f$ is supported on a compact interval. Assume A1 holds and $m=m_{n}=\log n / \log \log n$. Then $k^{-1} \sum_{i=1}^{k}\left\{\tilde{\psi}\left(u_{i}\right)-\right.$ $\left.\psi\left(u_{i}\right)\right\}^{2}=\mathcal{O}_{p}\left\{(\log n)^{2} / n\right\}$.

Proof. Let $\beta^{0}$ be the true value $\beta_{j}^{0}=\int \xi^{j-1} f(\xi) d \xi / j$ !. Write $Y=Z \beta+\varepsilon$, where $\varepsilon$ include both the random error and the bias terms due to both the estimator and the truncation. The latter term is given in (13). By standard least squares results

$$
\begin{aligned}
k^{-1} \mathrm{E} \sum_{i=1}^{k}\left\{\tilde{\psi}\left(u_{i}\right)-\psi\left(u_{i}\right)\right\}^{2} & =k^{-1} \mathrm{E}\left\{\varepsilon^{\top} Z\left(Z^{\top} Z\right)^{-1} Z^{\top} \varepsilon\right\} \\
& =k^{-1} \operatorname{trace}\left\{Z\left(Z^{\top} Z\right)^{-1} Z^{\top} \mathrm{E}\left(\varepsilon \varepsilon^{\top}\right)\right\} .
\end{aligned}
$$

Since $Z\left(Z^{\top} Z\right)^{-1} Z^{\top}$ is a projection matrix on a $m$-dimensional space, the RHS is bounded by the largest eigenvalue of $\mathrm{E}\left(\varepsilon \varepsilon^{\top}\right)$ times $m / k$. This has three sources
(variance and two biases) and hence

$$
k^{-1} \mathrm{E} \sum_{i=1}^{k}\left\{\tilde{\psi}\left(u_{i}\right)-\psi\left(u_{i}\right)\right\}^{2}=\mathcal{O}\left[\frac{m}{k}\left\{\frac{k}{n}+k \frac{\log n}{n}+k\left(\frac{b^{m}}{m!}\right)^{2}\right\}\right] .
$$

The factor $k$ before the last two terms is due to the norm of the unit vector in $\mathbb{R}^{k}$, and, the last term is by (13). The theorem follows by taking $m=\log n / \log \log n$

A more general result can be based on an assumption like the following
A2. Assume that for some $c, d$ and each $\varepsilon$ there are $h_{\varepsilon, 1}, \ldots, h_{\varepsilon, M(\varepsilon)}$ such that

$$
\sup _{\xi} \min _{\gamma} \max _{c<u<d}\left|g(u ; \xi)-\sum_{j=1}^{M(\varepsilon)} \gamma_{j} h_{j}(u)\right|<\varepsilon
$$

Note that clearly the assumption ensures the existence of $\gamma(\cdot)$ such that $\max _{c<u<d} \mid g(u ; \xi)-$ $\sum_{j=1}^{M(\varepsilon)} \gamma_{j}(\xi) h_{j}(u) \mid<\varepsilon$, but then there are also $\beta_{j}=\int \gamma_{j}(\xi) f(\xi) d \xi, j=1, \ldots, M(\varepsilon)$, such that $\max _{c<u<d}\left|\psi(u)-\sum_{j=1}^{M(\varepsilon)} \beta_{j} h_{j}(u)\right|<\varepsilon$.

The following theorem can be proved similarly to Theorem 4.2 :
Theorem 4.3 Suppose assumptions A1 and A2 hold. Define $\varepsilon_{n}$ by

$$
\varepsilon_{n}=\underset{\varepsilon}{\arg \min }\{M(\varepsilon) / n+\varepsilon\} .
$$

Let $\tilde{\psi}$ be the least squares estimate of the regression of $\hat{\psi}$ on $h_{\varepsilon_{n}, 1}, \ldots, h_{\varepsilon_{n}, M\left(\varepsilon_{n}\right)}$. Then $k^{-1} \sum_{i=1}^{k}\left\{\tilde{\psi}\left(u_{i}\right)-\psi\left(u_{i}\right)\right\}^{2}=\mathcal{O}_{p}\left(\varepsilon_{n}\right)$.

In practice, Theorems 4.2 and 4.3 may seem to be of a limited use - a knowledge of the structure of the span of the individual utility functions is needed, and the regression is based on an identified efficient base, which may be not natural. For example, we used a polynomial base for the exponential utility function. The practical approach is an histogram or discrete approximation of $f$. We want now to discuss when such a procedure does yield an effective estimator, an estimator which is both statistically speaking efficient, but at the same time easy to compute and can be be used in off-the-shelf manner.

This is indeed the case. Let $\xi_{1}, \ldots, \xi_{M(\varepsilon)}$ be reasonably spaced points in the support of $f$. With the notation introduced after Assumption A2, and by a similar argument, for a vector $\beta$ on the simplex

$$
\sup _{u}\left|\sum_{j=1}^{M(\varepsilon)} \beta_{j} g\left(u ; \xi_{j}\right)-\sum_{j=1}^{M(\varepsilon)} \beta_{j} \sum_{l=1}^{M(\varepsilon)} \gamma_{l}\left(\xi_{j}\right) h_{l}(u)\right| \leq \varepsilon .
$$

Hence, one can use the base function $g\left(\cdot ; \xi_{1}\right), \ldots, g\left(\cdot ; \xi_{M(\varepsilon)}\right)$ as well.

## Appendix A: Appendix: Proof of Theorem 4.1 .

We start the proof with the negative result. The proof is standard. We exhibit a small perturbation that cannot be detected. The perturbed density should remain a probablity density function with bounded second derivative. It should be however very wiggly so that the exponential mixing would smooth it out to make it hardly detectable through $\psi$. Very convenient candidates could be high derivatives of the normal density, but the supports of these functions are not bounded, while the support of $f$ is bounded at least from below. We therefore use derivatives of approximations of the normal density. Here are the details.

Consider

$$
\pi_{m}(\xi)=\pi_{m}(\xi ; c, d)=\left\{1-\left(\frac{\xi-c}{d}\right)^{2}\right\}^{m} \mathbf{1}\{\xi \in(c-d, c+d)\}
$$

for some $c, d$, where 1 denotes the indicator function. $\pi_{m}$ is approximately the normal pdf normalized improperly, cf. (24) below. Note that for $k \leq m$ :

$$
\begin{equation*}
\int_{c-d}^{c+d} e^{u \xi} \pi_{m}^{(k)}(\xi) d \xi=(-1)^{k} u^{k} \int e^{u \xi} \pi_{m}(\xi) d \xi \tag{14}
\end{equation*}
$$

and

$$
\begin{equation*}
\pi_{m}^{(2 k)}(c)=(-1)^{k} d^{-2 k}\binom{m}{k}(2 k)! \tag{15}
\end{equation*}
$$

Write

$$
\pi_{m}(\xi)=\left(1-\frac{\xi-c}{d}\right)^{m}\left(1+\frac{\xi-c}{d}\right)^{m}
$$

and taking the derivative of the RHS:

$$
\begin{align*}
& \pi_{m}^{2 k}(\xi) \\
& =d^{-2 k} \sum_{i=0}^{2 k}\binom{2 k}{i}(-1)^{i} \frac{m!}{(m-i)!}(1-\tilde{\xi})^{m-i} \frac{m!}{(m-2 k+i)!}(1+\tilde{\xi})^{m-2 k+i}  \tag{16}\\
& =d^{-2 k} \sum_{i=0}^{k}(-1)^{i} a_{i}, \quad \text { say. }
\end{align*}
$$

For simplicity we write $\tilde{\xi}=(\xi-c) / d$. Note that

$$
\frac{a_{i+1}}{a_{i}}=\frac{2 k-i}{i+1} \frac{m-i}{m-2 k+i+1} \frac{1+\tilde{\xi}}{1-\tilde{\xi}}
$$

Hence the sum in the RHS of (16) is of unimodal terms with alternating signs. Let $l$ be the index where the maximum is achieved:

$$
\begin{equation*}
\frac{2 k-l}{l+1} \frac{m-l}{m-2 k+l+1}=\{1+\circ(1)\} \frac{1-\tilde{\xi}}{1+\tilde{\xi}} \tag{17}
\end{equation*}
$$

Then

$$
\begin{align*}
a_{l} & \geq a_{l}-\sum_{j=1}\left(a_{l+2 j-1}-a_{l+2 j}\right)-\sum_{j=1}\left(a_{l-2 j+1}-a_{l-2 j}\right) \\
& =(-1)^{l} \sum_{i=0}^{2 k}(-1)^{i} a_{i}  \tag{18}\\
& =a_{l}-a_{l+1}+\sum_{j=1}\left(a_{l+2 j}-a_{l+2 j+1}\right)-a_{l-1}+\sum_{j=1}\left(a_{l-2 j}-a_{l-2 j-1}\right) \\
& \geq-a_{l}
\end{align*}
$$

where, if necessarily, the sequences are padded by zeros at the ends. But then for some $C=\mathcal{O}(1), C$ may vary from line to line:

$$
\begin{align*}
a_{l}= & (2 k)!\binom{m}{l}\binom{m}{2 k-l}(1-\tilde{\xi})^{m-l}(1+\tilde{\xi})^{m-2 k+l} \\
\leq & C(2 k)!\frac{m^{2 m}(1-\tilde{\xi})^{m-l}(1+\tilde{\xi})^{m-2 k+l}}{l^{l}(m-l)^{m-l}(2 k-l)^{2 k-l}(m-2 k+l)^{m-2 k+l}}  \tag{19}\\
= & C(2 k)!\left(1-\tilde{\xi}^{2}\right)^{m-2 k}\left\{\frac{k(1-\tilde{\xi})}{2 k-l}\right\}^{2 k-l}\left\{\frac{k(1+\tilde{\xi})}{l}\right\}^{l}\left\{\frac{m}{k}\right\}^{2 k} \\
& \times\left\{1+\frac{l}{m-l}\right\}^{m-l}\left\{1+\frac{2 k-l}{m-2 k+l}\right\}^{m-2 k+l}
\end{align*}
$$

To deal with the following terms of the RHS of (19) we assume that $0<l \leq k$. The case $2 k>l \geq k$ is dealt similarly. The cases of $l \in\{0,2 k\}$ are simple

$$
\begin{align*}
\left\{\frac{k(1-\tilde{\xi})}{2 k-l}\right\}^{2 k-l}\left\{\frac{k(1+\tilde{\xi})}{l}\right\}^{l} & =\left\{\frac{k(1-\tilde{\xi})}{2 k-l}\right\}^{2(k-l)}\left\{\frac{1+\tilde{\xi}}{1-\tilde{\xi}} \frac{2 k-l}{l}\right\}^{l} \\
& \leq 2^{k}\left\{\frac{1+\tilde{\xi}}{1-\tilde{\xi}} \frac{2 k-l}{l+1}\right\}^{l}  \tag{20}\\
& \leq 3^{k}\left\{\frac{m-2 k+l+1}{m-l}\right\}^{l}, \quad \text { by }(17) \\
& \leq 3^{k}
\end{align*}
$$

The next bound is easy,

$$
\begin{equation*}
\left\{1+\frac{l}{m-l}\right\}^{m-l}\left\{1+\frac{2 k-l}{m-2 k+l}\right\}^{m-2 k+l}<e^{2 k} \tag{21}
\end{equation*}
$$

since $(1+1 / x)^{x}<e^{x}$ for any $x>0$. We conclude from (16), (18), (20), and (21):

$$
\begin{equation*}
\left\|\pi_{m}^{(2 k)}\right\|_{\infty} \leq a_{l} \leq C(2 k)!\left\{c_{2} \frac{m}{k}\right\}^{2 k} \tag{22}
\end{equation*}
$$

for $c_{2}>1$.

Let

$$
\Delta_{m, k}(\xi)=\frac{d^{2 k}}{(2 k+2)!\left(c_{1} c_{2}\right)^{2 k}} \pi_{m}^{(2 k)}(\xi)
$$

where we take $m=\left\lceil c_{1} k\right\rceil$. Note that by (22) $\Delta_{m, k}^{(2)}$ is uniformly bounded, while by (15)

$$
\begin{equation*}
\Delta_{m, k}(c) \geq c_{3} k^{-2}\left(c_{1} c_{2}\right)^{-2 k}\binom{m}{k} \geq c_{4}^{-k} \tag{23}
\end{equation*}
$$

for some $c_{4}>1$. However by (14)

$$
\begin{aligned}
\int \xi^{-1} & \left\{e^{u \xi}-1\right\}\left\{f(\xi)+\xi \Delta_{m, k}(\xi)\right\} d \xi \\
& =\psi(u)+\frac{d^{-2(m-k)}}{(2 k+2)!c_{2}^{2 k}} u^{2 k} \int_{a}^{b} \pi_{m}(\xi) e^{u \xi} d \xi \\
& =\psi(u)+(-1)^{k}\{1+\odot(1)\} \frac{d^{2 k}}{(2 k+2)!c_{2}^{2 k}} u^{2 k} \int_{a}^{b} e^{-m(\xi-c)^{2} / d^{2}} e^{u \xi} d \xi \\
& =\psi(u)+(-1)^{k}\{1+७(1)\} \frac{\sqrt{2 \pi} d^{2 k+1}}{(2 k+2)!m^{1 / 2} c_{2}^{2 k}} u^{2 k} e^{u c}
\end{aligned}
$$

Hence if

$$
\frac{d^{2 k+1}}{(2 k+2)!m^{1 / 2}\left(c_{1} c_{2}\right)^{2 k}}=\bigcirc\left(n^{-1 / 2}\right)
$$

or $k \log k-\log n \rightarrow \infty$, then one would not be able to test between $f$ to $f+$ $\xi \Delta_{m, k}$. In particular this happens when $k=\log n / \log \log n$. However, then, by (23), $n^{\alpha} \Delta_{m, k}(c) \rightarrow \infty$ for any $\alpha>0$. This proves that $f$ can be estimated in any $n^{\alpha}, \alpha>0$ rate.

We move now to the positive result. We suggest an estimator of the mixing density $f$ whose rate of convergence is easy to evaluate. Of course, the practical way would be the standard least squares as discussed in Subsection 4.3 , but then rates are difficult to evaluate. We suggest therefore in the proof a kernel estimator of $g$ given by $\int \hat{\psi}(u) \bar{K}(u) d u$ for some $\bar{K}$ given below. Here are the details.

If $\psi(u)=\int g(u ; \xi) f(\xi) d \xi$, let $\psi_{s}=\psi_{s}(u)=e^{-u s}(\psi(u)-1)$. Assume for simplicity that by assumption $f(\xi)=0$ for $\xi \notin\left(s_{0}-d, s_{0}+d\right)$. Then since

$$
\begin{aligned}
\psi_{s}(u) & =\int e^{u(\xi-s)} \xi^{-1} f(\xi) d \xi-e^{-u s} \int \xi^{-1} f(\xi) d \xi \\
\psi_{s}^{(k)}(u) & =\int(\xi-s)^{k} e^{u(\xi-s)} \xi^{-1} f(\xi) d \xi-(-1)^{k} s^{k} e^{-u s} \int \xi^{-1} f(\xi) d \xi
\end{aligned}
$$

then formally:

$$
\sqrt{\frac{m}{2 \pi d^{2}}} \sum_{k=0}^{m}\binom{m}{k}\left\{\frac{-1}{d^{2}}\right\}^{k} \psi_{s}^{(2 k)}(u)
$$

$$
\begin{aligned}
& =\sqrt{\frac{m}{2 \pi d^{2}}} \int \pi_{m}(\xi ; s, d) e^{u(\xi-s)} \xi^{-1} f(\xi) d \xi \\
& \quad-\sqrt{\frac{m}{2 \pi d^{2}}} \pi_{m}(s ; 0, d) e^{-u s} \int \xi^{-1} f(\xi) d \xi
\end{aligned}
$$

where $\pi_{m}(\cdot)=\pi_{m}(\cdot ; s, d)$. Note that for any smooth bounded function $h$ with two bounded derivatives:

$$
\begin{align*}
\sqrt{\frac{m}{2 \pi d^{2}}} \int \pi_{m}(\xi ; s, d) h(\xi) d \xi & \approx \sqrt{\frac{m}{d^{2}}} \int \varphi\{\sqrt{m}(\xi-s) / d\} h(\xi) d \xi  \tag{24}\\
& \approx h(s)+\mathcal{O}\left(m^{-1}\right)
\end{align*}
$$

where $\varphi$ is the standard normal density. Hence

$$
\begin{equation*}
\sqrt{\frac{m}{2 \pi d^{2}}} \sum_{k=0}^{m}\binom{m}{k}\left(\frac{-1}{d^{2}}\right)^{k} \psi_{s}^{(2 k)}(u) \rightarrow s^{-1} \xi(s) \quad \text { as } m \rightarrow \infty \tag{25}
\end{equation*}
$$

Let $\hat{\psi}_{s}$ be an estimator of $\psi_{s}$. Let $K$ be a smooth kernel of order $2 m$, integrated to 1 , and with bounded support kernel. Then by (25) we can estimate $f(s)$ by

$$
\begin{align*}
\hat{f}(s) & =s \sqrt{\frac{m}{2 \pi d^{2}}} \sum_{k=0}^{m}\binom{m}{k}\left(\frac{-1}{d^{2}}\right)^{k} \int K(u) \hat{\psi}_{s}^{(2 k)}(u) d u \\
& =s \sqrt{\frac{m}{2 \pi d^{2}}} \sum_{k=0}^{m}\binom{m}{k}\left(\frac{-1}{d^{2}}\right)^{k} \int K^{(2 k)}(u) \hat{\psi}_{s}(u) d u  \tag{26}\\
& =\int \bar{K}(u) \hat{\psi}_{s}(u) d u
\end{align*}
$$

where

$$
\bar{K}(u) \equiv s \sqrt{\frac{m}{2 \pi d^{2}}} \sum_{k=0}^{m}\binom{m}{k}\left(\frac{-1}{d^{2}}\right)^{k} K^{(2 k)}(u)
$$

Since we have already developed the machinery we pick

$$
K(u)=\gamma_{m} \sqrt{\frac{2 m}{2 \pi \sigma^{2}}} \pi_{2 m}\left(u ; u_{0}, \sigma\right)
$$

where $\gamma_{m}=1+o(1)$. Hence by (22)

$$
\begin{equation*}
\|\bar{K}\|_{\infty} \leq s \frac{m}{2 \pi \sigma d} \sum_{k=0}^{m}\binom{m}{k}\left(\frac{c m}{k}\right)^{2 k}(2 k)!=\mathcal{O}\left(c^{m} m^{m}\right) \tag{27}
\end{equation*}
$$

If $\psi_{s}$ can be estimated at a standard polynomial rate, $\hat{\psi}-\psi=\mathcal{O}_{p}\left(n^{-\gamma}\right)$, then we obtain from (26) and (27) that $\hat{\psi}$ induce an error of $\mathcal{O}\left(c^{m} m^{m} / n^{\gamma}\right)$. To this we
have to add the bias of $\mathcal{O}\left(m^{-1}\right)$ as given by (24). The minimization of the error estimate is obtained therefore of the order of the value at $m$ when these two terms are equal:

$$
m \log m-\gamma \log n=\log m
$$

By taking $m=m_{n}=\alpha \log n / \log \log n$ we achieve the rate of

$$
\hat{f}(s)-f(s)=\mathcal{O}_{p}\left(n^{-\alpha \log \log n / \log n}\right),
$$

for any $\alpha<1$. We have shown that the optimal rate of convergence is $n^{\alpha_{n}}$ for some $\alpha_{n} \rightarrow 0$ slowly.
